Natural Convection Measurements for a Concentric Spherical Enclosure

An experimental test program is described for the measurement of natural convection for an isothermal, heated sphere centrally located in an isothermal, cooled spherical enclosure. A transient test method is used in a reduced pressure environment to provide data for a wide range of Rayleigh number, from the limiting case of laminar boundary layer convection to the diffusive limit. Tests are performed using a fixed outer diameter for four different inner sphere diameters, resulting in diameter ratios in the range 1.5 ≤ \( d_i/d_o \) ≤ 4.8. The data are in excellent agreement with the exact solution for the conductive limit and are shown to be bounded by a model for the isolated, isothermal sphere.

[DOI: 10.1115/1.2188476]

Introduction

The problem of natural convection in the enclosed region formed between an isothermal heated body and its surrounding, isothermal cooled enclosure is currently of some interest to designers of microelectronics equipment. In an effort to protect electronics from environmental contaminants such as dust or moisture, circuits are often housed in sealed enclosures, especially in outside plant applications. The ability to model natural convection heat transfer within these sealed enclosures would be of great benefit providing quick and easy-to-use design tools for preliminary design tasks such as parametric studies and trade-off analysis.

Research is currently underway to develop analytically based models to predict convective heat transfer in these systems. Of particular importance to the model development process is the enclosure formed between isothermal concentric spheres, the most fundamental type of doubly connected enclosure. It is anticipated that the lessons learned during the development of a natural convection model for the concentric spheres will be directly applicable to more complex enclosure geometries.

One of the most important elements in the development of analytical models is the availability of experimental data over the full range of the independent parameters. Accurate data are vital in order to reveal trends, such as limiting cases or transition behavior, and for the validation of the completed models. The current literature contains only a limited set of experimental data for the isothermal concentric sphere problem from Bishop et al. [1], Scanlan et al. [2], Weber et al. [3] and Powe et al. [4]. Bishop et al. [1] performed air measurements at atmospheric pressure for a single outer sphere diameter and four inner sphere diameters, leading to diameter ratios of \( d_i/d_o = 1.25, 1.67, 2.0, \) and 2.5. Scanlan et al. [2] performed measurements for water and silicon oil-filled spherical enclosures, with \( 4.7 \leq \text{Pr} \leq 4.148 \) for five diameters ratios ranging from \( d_i/d_o = 1.09 \) to 2.81. The data are limited to a narrow range of high Rayleigh numbers indicative of the boundary layer flow limit. Weber et al. [3] repeated the measurements of Scanlan et al. [2] for vertically eccentric enclosures and Powe et al. [4] present a photographic study of flow patterns between an arbitrarily shaped body and its spherical enclosure, of which the concentric spheres is a special case. The remaining data available in the literature are derived from numerical simulations of the spherical enclosure, including those presented by Mack and Hardee [5], Astill et al. [6], Caltagirone et al. [7], Singh and Chen [8], Ingham [9], Wright and Douglass [10], Fujii et al. [11], Garg [12], Chu and Lee [13] and Chiu and Chen [14]. There are no experimental data in the current literature for the isothermal concentric spherical enclosure valid for the full range of Rayleigh number that includes the transition from convection to conduction-dominated heat transfer.

The objective of the current study is to perform measurements of natural convection heat transfer for isothermal concentric spheres for the full range of Rayleigh number, from the laminar boundary layer flow limit to the conductive limit. The procedure for performing the measurements will be developed, the apparatus will be described, and data for four different diameter ratios will be presented.

Problem Definition

The problem of interest involves convective heat transfer from a sphere, diameter \( d_o \), to a concentric spherical shell with inner diameter \( d_i \), as shown in Fig. 1. Isothermal boundary conditions exist at both the inner and outer boundaries, as follows:

- Inner boundary: \( T = T_i \)
- Outer boundary: \( T = T_o \)

where \( T_i > T_o \). The total heat transfer rate through the enclosed region is determined at the inner boundary by

\[
Q = \int \int_{A_i} -k \frac{\partial \theta}{\partial n} dA, \quad \theta = T(\vec{r}) - T_b \tag{1}
\]

where \( T(\vec{r}) \) is the temperature distribution adjacent to the inner boundary along an outward-facing normal, and \( T_b \) is the bulk fluid temperature in the enclosure. Assuming constant fluid properties and nondimensionalizing yields the dimensionless total heat transfer rate

\[
Q^* = \frac{Q L}{k A_i (T_i - T_b)} = \frac{L}{A_i} \int \int_{A_i} -\frac{\partial \phi}{\partial n} dA \tag{2}
\]

where \( L \) is a general scale length and the dimensionless temperature excess \( \phi \) is defined as...
The Rayleigh number is defined by

\[ \text{Ra} = \frac{g \beta \Delta T L^3}{\nu \alpha} \]  

(6)

where \( g \) is the gravitational acceleration, \( \beta \) is the temperature coefficient of the fluid, \( \Delta T \) is the temperature difference, \( L \) is the characteristic length, \( \nu \) is the kinematic viscosity, and \( \alpha \) is the thermal diffusivity.

The average heat transfer coefficient for the enclosure \( h \) is defined based on the average heat flux at the inner boundary and the overall temperature difference

\[ h = \frac{(Q/A)}{\Delta T} \]  

(4)

where \( \Delta T = T_i - T_o \). Nondimensionalizing \( h \) using the general scale length \( L \) gives the area-mean Nusselt number, which can be shown to be equivalent to the dimensionless heat transfer rate

\[ \text{Nu} = \frac{hL}{k} = \frac{Q/L}{kA \Delta T} = \text{Nu}_c \]  

(5)

The conduction shape factor is related to the thermal resistance by

\[ S_c^* = \frac{1}{kL} \]  

(10)

Using the exact solution for the thermal resistance of a concentric spherical shell [19], the conduction shape factor is

\[ S_c^* = \frac{2L}{d_i(1 - d_i/d_o)} \]  

(11)

Since the problem of interest involves only spherical body shapes and the size of the inner sphere is the only variable geometric parameter, the diameter of the inner sphere is selected as the scale length for all dimensionless parameters, such that \( L = d_i \).

Experimental Apparatus

In order to perform the required measurements, an experimental apparatus was created consisting of a single, spherical enclosure, and a series of inner spheres of various diameters. The outer spherical enclosure was constructed of two aluminum blocks with hemispherical cavities machined into one side, as shown in Fig. 2, so as to form a spherical shell when joined together. Aluminum 6061 was used due to its high value of thermal conductivity to provide a near-isothermal boundary condition, and the hemispherical surfaces were polished to minimize radiation heat transfer.

The size of the enclosure was selected based on two main criteria. First, because many of the tests were to be performed at reduced pressures, it was necessary that the maximum dimensions of the apparatus not exceed the space available within the available vacuum chamber. Second, in order to avoid rarefaction effects the gap spacing between the inner and outer boundaries \( \delta \) had to be much larger than the mean free path of gas \( \lambda \) as defined by the Knudsen number

\[ Kn = \frac{\lambda}{\delta} \]  

(12)

The mean free path of air as a function of pressure and temperature can be determined by [18]

\[ \lambda = 6.4 \times 10^{-10} \left( \frac{1}{p(\text{atm})} \right) \left( \frac{T(\text{K})}{288} \right) (\text{m}) \]  

(13)

Ensuring that \( Kn < 0.01 \) for the full range of pressures and temperatures anticipated in the experimental program provides a lower limit for the outer sphere dimensions. Based on these two
criteria, the dimensions of the outer enclosure were chosen such that its diameter was \( d_o = 120 \) mm.

In order to provide data for a wide range of diameter ratios, four different spherical inner bodies were machined from 6061 aluminum. The diameters of the spheres and the resulting diameter ratios are given in Table 1. Each sphere was suspended at the center of the enclosure using a 4–6 mm diameter threaded phenolic rod turned into tapped holes on both the inner and outer enclosure walls, as shown in Fig. 3. All wiring to the inner sphere was connected through a single, 6 mm diameter hole at the top of the enclosure.

All temperature measurements were performed using T-type copper-constantan thermocouples affixed at the surfaces of the inner and outer spheres in shallow, small diameter holes using aluminum-filled epoxy. The temperature at the outer surface of the enclosure was measured using six 30 AWG (0.254 mm) thermocouple wires distributed at the top, bottom, and midplane, while the two thermocouples at the top and bottom of the inner body used smaller diameter, 36 AWG (0.127 mm) wires to reduce conduction losses. All thermocouples measurements were based on an external reference junction that was maintained at 0±0.1°C by an ice point cell.

Each of the inner spheres were heated using an embedded dc-powered cartridge heater. Constantan wires were used for all connections rather than copper to reduce heat losses through the wires; 24 AWG (0.508 mm) to provide power to the heaters and 36 AWG to measure voltage. The current to the heater was measured using a calibrated shunt resistor.

The outer enclosure walls were cooled by six cold plates attached on the exterior surface of the blocks using thermally conductive grease at the joints. Heat was removed from the system using a glycol-water mixture circulated through the cold plates by a constant temperature bath.

Once assembled, the enclosure test apparatus was placed in vacuum chamber, as shown in Fig. 4, with feedthroughs available for the coolant, electrical, and instrumentation connections. The vacuum chamber used in this work uses a dual-pump system: a mechanical roughing pump capable of providing reduced pressure test conditions suitable for the convection tests and a diffusion pump for producing a totally evacuated environment for radiation heat transfer testing. The vacuum system also contains a high accuracy vacuum gauge suitable for absolute readings in the range 0.001–1 atm.

Data acquisition and control of the experiment was performed using a Keithley 2700 data acquisition system and a Windows-based PC computer running LABVIEW v5.1 software.

**Measurement Procedure**

The heat transfer rate due to convection through the enclosure \( Q \) can be determined based on an energy balance on the inner boundary

\[
Q = Q_{\text{tot}} - Q_{\text{rad}} - Q_t
\]

where \( Q_{\text{tot}} \) is the total heat transfer due to all modes, \( Q_{\text{rad}} \) is the net radiative heat transfer between the inner and outer surfaces, and \( Q_t \) are the accumulated conduction losses through the wires. In order to predict \( Q \), a means is required whereby the total heat transfer rate can be measured, along with a method to quantify the losses due to radiation and conduction.

**Total Heat Transfer Rate.** The simplest method to determine the total heat transfer rate \( Q_{\text{tot}} \) is through a direct measurement of electrical energy dissipated by the heater during a steady-state test. A fixed voltage would be applied to the heater and body temperatures would be monitored until sufficient time had elapsed such that the temperature change is less than some specified criteria. Then, the total heat transfer rate would be determined by

\[
Q_{\text{tot}} = VI
\]

where \( V \) and \( I \) are the heater voltage and current, respectively.

Hollands [16] reports that, in the case of natural convection in
gases, approximately five times the time constant \( 5\tau \) is required to achieve steady-state conditions, where the time constant is defined as

\[
\tau = mc_p R
\]  

(15)

Due to the relatively large values of the heat capacity \( mc_p \) and the average thermal resistance \( R \) for the proposed tests, especially those to be performed in a reduced pressure environment, steady-state testing becomes a prohibitively time-consuming option. Instead, the current study will implement the transient test method of Hollands [16] that allows convective heat transfer measurements to be performed in a fraction of the time required for steady-state tests. This method is based on the assumption that, due to the slow rate of change of body temperature, a "quasi-steady" condition exists where the convective heat transfer is virtually identical to the steady-state results at the same temperature.

The use of a transient test to measure steady-state convection in the enclosure can be validated by a comparison of the time constants for the inner body and the enclosed air layer for the worst case condition, the smallest sphere, \( \tau_i \), at atmospheric pressure. Using Eq. (15) and textbook values [19] for the ther-physical properties \( \rho \) and \( c_p \), the time constant for the sphere is determined as a function of the film resistance at the inner boundary

\[
\tau_i = \left( \frac{2770 \text{ kg}}{m^3} \right) \left( 8.18 \times 10^{-6} \text{ m}^3 \right) \left( 875 \text{ J kg}^{-1} \text{ K}^{-1} \right) R_i = 19.8 \cdot R_i
\]

(16)

The time constant for the enclosed air layer \( \tau_b \) is determined using the same method

\[
\tau_b = \left( \frac{1.1614 \text{ kg}}{m^3} \right) \left( 8.97 \times 10^{-4} \text{ m}^3 \right) \left( 1007 \text{ J kg}^{-1} \text{ K}^{-1} \right) R_o = 1.05 \cdot R_o
\]

(17)

where \( R_o \) is the film resistance at the outer boundary. Assuming that the film resistances at the inner and outer surfaces are similar \( R_i = R_o \), the ratio of the time constants can be calculated

\[
\frac{\tau_i}{\tau_b} = 19
\]

(18)

With a factor of 20 difference between the time constants for the worst case conditions, it is therefore reasonable to assume that the cooling rate of the inner body will control the heat transfer and that a "quasi-steady" condition exists in the enclosed fluid region.

In the transient test method, the body is heated to some initial, specified temperature while the temperature of the enclosure remains constant throughout the test. When the prescribed temperature difference is reached, the power to the heater is turned off and the transient response of the inner body is monitored. Measurements continue until \( \Delta T \) falls below some minimum prescribed value. The total heat transfer rate at any time \( t \) and corresponding temperature difference \( \Delta T \) can be determined based on the transient data by

\[
Q_{tot} = -mc_p \frac{dT(t)}{dt}
\]

(19)

where the heat capacity of the inner body \( mc_p \) is determined empirically using a method described in the next section. The time derivative in Eq. (19) is approximated for distinct time intervals \( t_n \) using a least-squares method to predict the slope of sets of 101 average inner body temperature versus time data points.

\[
\frac{dT}{dt} \mid_{t_n} = \text{slope} (T_i \ vs. \ t) \text{ for } 1 \leq j \leq 101
\]

(20)

Then, \( Q_{tot} \) can be calculated for time \( t_n \), corresponding to the time value of the middle data point.
Heat Capacity and Radiative Losses. The simplest method for determining the heat capacity of an isotropic body is to measure its mass and multiply by a tabulated value for specific heat capacity value from a handbook. However, in the case of the current study the inner spheres are not homogeneous but instead contain an embedded cartridge heater, a section of the phenolic mounting rod, and thermocouples. The radiation heat transfer through the enclosure could also be modeled using available analytical techniques, but without precise values for the emissivity of the inner and outer boundaries, it is difficult to produce accurate results. Therefore, both the heat capacity and the radiative heat transfer for each test case will be determined based on empirical data.

In order to provide an effective measure of both quantities, a two-stage test procedure is used. Starting at an initial condition \( \Delta T = 0 \), a heating test to a maximum value of \( \Delta T \) is performed to determine the heat capacity, followed immediately by a cooling test back to a final \( \Delta T \) value to measure radiative losses. For high vacuum conditions, such that \( Kn > 100 \), it can be assumed that gaseous convection and conduction are eliminated and heat transfer occurs by radiation alone. The energy balance for the inner body for any time \( t \) is

\[
mc_p \frac{dT_i}{dt} = V \cdot I - Q_{\text{rad}} - Q_L \tag{22}
\]

In the heating test the constant value of electrical power \( V \cdot I \) provided to the heater can be assumed to be large enough such that the conduction losses are minimal, \( Q_L = 0 \), and \( Q_{\text{rad}} \) is assumed to be a linear function of the factor \( \sigma(T_i^4 - T_o^4) \). Then Eq. (22) becomes

\[
\frac{dT_i}{dt} = \frac{V \cdot I}{mc_p} - \frac{C_{\text{rad}} \sigma(T_i^4 - T_o^4)}{mc_p} \tag{23}
\]

where \( C_{\text{rad}} \) is assumed to be constant for each test body. Using a least-squares method to determine the time gradient of the inner body temperature, as described in the previous section, values of \( dT_i/dt \) can be plotted versus the radiation parameter \( \sigma(T_i^4 - T_o^4) \), as shown in Fig. 7. Based on Eq. (23) it can be seen that the y intercept predicted by the linear fit of the data in Fig. 7 can be used to calculate the heat capacity of the body. The empirical predictions for the heat capacity of each of the inner spheres tested are presented in Table 2.

Once the maximum \( \Delta T \) value had been achieved, the heater was shut down, \( V \cdot I = 0 \), reducing Eq. (22) to

\[
Q_{\text{rad}} = -mc_p \frac{dT_i}{dt} - Q_L \tag{24}
\]

where \( Q_L \) is assumed to be zero for all but the heat conduction through the mounting rod, modeled using a simple one-dimensional relationship

\[
Q_{\text{rod}} = \frac{\delta}{k_{\text{rod}} \pi(d_{\text{rod}}/2)^2} \tag{25}
\]

The thermal conductivity of the phenolic rod material is \( k_{\text{rod}} = 0.4 \) W/mK, \( \delta \) is the enclosure gap spacing, and \( d_{\text{rod}} \) is the rod diameter. The time gradient of the average inner body temperature \( dT_i/dt \) is determined using the least-squares approximation and the corresponding heat capacity value from the heating test. Figure 8 presents the measured values of \( Q_{\text{rad}} \) versus the radiation parameter \( \sigma(T_i^4 - T_o^4) \) and least-square fits of these data according to the relationship

\[
Q_{\text{rad}} = C_{\text{rad}} \sigma(T_i^4 - T_o^4) \tag{26}
\]

Values for the radiation correlation coefficient for each body are presented in Table 2.

Conduction Losses. There are four potential sources of conductive heat loss from the inner body: the power wires, the voltage measurement leads, the thermocouples, and the connecting rod. This analysis will consider losses by convection from the wires only; it is assumed that losses due to radiation from the wires have been accounted for by the correlation of the radiation test data and conduction losses through the connecting rod will be

Table 2 Heat capacity and radiation coefficient values for inner spherical bodies
The temperature drop has occurred

Solving for the effective fin length gives

where \( T_b \) is the mean of the inner and outer boundary temperatures

and \( \text{heat dissipation coefficient value} \) is an effective fin length. Convective heat transfer from the insulation is modeled as an infinitely long, horizontal circular cylinder [20]

where \( d_{\text{ins}} \) and \( k_{\text{ins}} \) are the diameter and thermal conductivity of the insulation and \( L_e \) is an effective fin length. Convective heat transfer from the insulation is modeled as an infinitely long, horizontal circular cylinder [20]

where \( h = \frac{k}{d_{\text{ins}}} \) is an effective fin length. Convective heat transfer from the insulation is modeled as an infinitely long, horizontal circular cylinder [20]

while the average wire temperature is determined from an integral of the temperature profile of the infinitely long fin

where \( L_e \) is the effective fin length, determined by solving the temperature distribution equation for the \( x \) location where 95% of the temperature drop has occurred

Solving for the effective fin length gives

Substituting and solving for the average wire temperature yields

In the case of the thermocouple wires, where two insulated wires are wrapped together with an additional insulation layer, effective wire and insulation diameters and thermal conductivity are used in the preceding calculations, as described by Sparrow [21]

\( d_{\text{eff}} = \sqrt{2} d_{\text{ins}}, \quad \text{min} = \frac{\lambda_1 + \lambda_2}{2}, \quad k_{\text{eff}} = k_{\text{ins}} + k_{\text{ins}} \)

where \( \lambda_1 \) and \( \lambda_2 \) are the cross-sectional dimensions of the insulation.

Calculation of the conduction losses through each of the wires and reduction of \( Q_{C} \) from the results leads to values of \( Q \) that are less than those of the pure conduction model, Eq. (11), when the pressure has been sufficiently reduced that the data has reached the diffusive limit and become independent of \( \text{Ra} \). It is assumed

that this overprediction of the wire loss is due to the approximations used in the model formulation, including the assumptions of a horizontal circular cylinder geometry and infinite fin length. Due to the complexity of the problem, it may be impossible to formulate a model to accurately predict all conduction losses from the heated body. Therefore, an empirically derived coefficient \( C_i \) is introduced to correct the model predictions.

Assuming that the wire loss model correctly accounts for the variations in temperature and gas pressure and provides a maximum value for the total heat loss by conduction, a coefficient having a range of values \( 0 < C_i < 1 \) is used to adjust the model as follows:

where \( Q_{C,i} \) are the model predictions for heat loss from each of the \( N \) wires. The value of \( C_i \) for a particular test setting is determined so as to minimize the % difference between the data and the conduction model, Eq. (11), when the pressure has been sufficiently reduced that the data has reached the diffusive limit. Values of \( C_i \) and the relative portion of the overall heat transfer attributed to conduction losses through the wires are given in Table 3 for each test case. The differences in \( C_i \) values in Table 3 are due to variations in wire length, material and orientation as well as body and heater size.

**Test Method.** With the measurement procedure and data reduction techniques defined, the test method is established as follows:

1. Assemble test body in enclosure, fit cold plates, and install complete assembly in chamber.
2. Seal vacuum chamber and start mechanical and diffusion pumps to establish high vacuum conditions (Kn > 100).
3. Perform heat capacity and radiation heat transfer tests.
4. Analyze data to obtain \( m_{\text{cp}} \) and \( Q_{\text{rad}} \) correlation.
5. Perform convective heat transfer measurements, starting at atmospheric conditions.
6. Reduce air pressure in chamber and repeat convection measurements, such that at least two tests are performed per decade of \( \text{Ra}_{d_i} \) and the data overlaps.
7. Continue reducing pressure and repeating convection tests until diffusive limit is achieved for at least two decades of Rayleigh number.
8. Analyze data to correct for conductive losses.

**Results.** Measurements were performed for each of the four inner sphere diameters given in Table 1 according to the test method described in the previous section. The enclosure was maintained at a constant temperature of 22°C, and the starting and ending values for the temperature difference for the transient convection tests were 50, and 10°C, respectively. Figure 9 presents all data collected for the \( d_{\text{ins}}/d_{\text{eff}} = 2 \) tests, and demonstrates the overlap between data for subsequent tests performed at different pressure levels. Data are selected from each pressure range to provide a smooth transition and a continuous set of data over the full range of Rayleigh number. The resulting final data sets for each of the four enclosure geometries are plotted in terms of the dimensionless parameters \( \text{Nu}_{d_i} \) and \( \text{Ra}_{d_i} \) in Fig. 10.
A full uncertainty analysis was performed to evaluate the impact of the accuracy of each of the instruments and sensors used in the experiments, along with the experimental method and data reduction techniques, on the reported values of Nusselt and Rayleigh numbers. The procedure used for the uncertainty analysis was based on the method described by Moffat [22]. Accuracy of the thermocouple readings (±0.2°C), heater voltage and current measurements, vacuum transducer measurements, dimensions, thermophysical properties, and time readings were combined to form an overall uncertainty on the Nusselt number of 2.1–2.3%, while the uncertainty in the Rayleigh number varied from 1.4% to 3.4%. Error bars are included in Fig. 10 that represent the uncertainty in the data associated with both the Rayleigh and Nusselt numbers.

A number of observations can be made concerning the data and its trends, as seen in Fig. 10. First, the goal of this work, to conduct measurements over a wide range of Rayleigh number, has been achieved with data being generated over at least four decades of Rayleigh numbers in all cases. Second, the data are in excellent agreement with the conductive limit and show independence of Ra for at least two decades of Rayleigh numbers. Finally, the data indicate a smooth transition from convection to conduction-dominated heat transfer that occurs within a single decade of the Rayleigh number.

In Fig. 10 a model for the isolated, isothermal sphere [23] is included, which is equivalent to the limit of an infinitely large enclosure, $d_i/d_i \rightarrow \infty$

\[ \frac{d_i}{d_i} = 2.0 \]

\[ \frac{d_i}{d_i} = 1.5, 2.0, 3.0, 4.8 \]

\[ \text{Isolated sphere} \]

\[ d_i/d_i \rightarrow \infty \]

\[ S'_{d} = 6.0 \]

\[ S'_{d} = 4.0 \]

\[ S'_{d} = 3.0 \]

\[ S'_{d} = 2.53 \]

\[ N_{u_i, d} = S'_{d} + F(Pr)G_{d_i} R_{a_d}^{1/4} \]

where the diffusive limit $S'_{d} = 2$ and the body gravity function $G_{d_i} = 0.879$ for the sphere. The value for the Prandtl number function for air at STP is $F(Pr) = 0.513$. As expected, the isolated sphere model provides an upper bound to the data at the laminar boundary layer flow, high Rayleigh number limit. From Fig. 10 it can be seen that for $d_i/d_i = 4.8$, the dimensions of the enclosure in relation to that of the inner body are large enough such that the system behaves similar to the isolated sphere. As $d_i/d_i$ decreases, the enclosure walls start to have a larger effect, leading to a reduction in the heat transferred for a given value of $\Delta T$.

Figure 11 compares the experimental data of the present study with the air data of Bishop et al. [1] for $d_i/d_i = 2$. The Bishop data were measured for larger values of Rayleigh number than were possible in the current test apparatus, so a direct comparison of the data cannot be performed. However, by extrapolating a best fit line from the present data as shown by the dashed line in Fig. 11, the good agreement between the measurements, and the data of Bishop et al. [1] can be demonstrated.

Summary

An experimental procedure and apparatus for performing measurements of natural convection between an isothermal sphere and its surrounding enclosure have been described. The goal of the research project, to provide data over a wide range of Rayleigh numbers including the transition and diffusive limit, was achieved through the use of a transient test procedure performed in a reduced pressure environment. The proposed transient test method was shown to produce highly accurate data in a much shorter time than the more traditional, steady-state methods. Four different inner spherical bodies were tested and the data were shown to be bounded by the limiting case of natural convection from an isolated, isothermal sphere.

\( R \) = thermal resistance, \( K/W \)
\( R \) = gas constant for air at STP, \( 287 \ J/kgK \)
\( R_a \) = Rayleigh number, \( = g\beta\Delta T L^3/(\rho a) \)
\( S^2_c \) = conduction shape factor, \( = QL/(kA\Delta T) \)
\( t \) = time, \( s \)
\( T \) = temperature, \( ^\circ C \)
\( T \) = average temperature, \( ^\circ C \)
\( \Delta T \) = temperature difference, \( = T_i - T_o \), \( ^\circ C \)
\( V \) = heater voltage \( V \)
\( Z \) = compressibility factor

Greek
\( \alpha \) = thermal diffusivity, \( m^2/s \)
\( \beta \) = thermal expansion coefficient, \( 1/K \)
\( \delta \) = gap thickness, \( = (d_o - d_i)/2 \), \( m \)
\( \phi \) = dimensionless temperature excess
\( \lambda \) = mean free path, \( m \)
\( \Lambda \) = thermocouple wire dimensions, \( m \)
\( \mu \) = dynamic viscosity, \( N s/m^2 \)
\( \nu \) = kinematic viscosity, \( m^2/s \)
\( \rho \) = mass density, \( kg/m^3 \)
\( \sigma \) = Stefan-Boltzmann constant, \( W/m^2 K^4 \)
\( \tau \) = time constant, \( = mc_p R \), \( s \)
\( \theta \) = temperature excess
\( \xi \) = fin parameter, \( 1/m \)
\( \zeta \) = radiation parameter, \( = \sigma(T_i^4 - T_o^4) \), \( W/m^2 \)

Subscripts
\( b \) = bulk fluid
\( i \) = inner body
\( o \) = outer body
\( \text{cond} \) = conduction
\( \text{conv} \) = convection
\( \text{rad} \) = radiation losses
\( \text{eff} \) = effective
\( \text{tot} \) = total
\( \ell \) = conduction losses

\( w = \) wire conductor
\( \text{ins} = \) wire insulation

Superscript
\( * = \) dimensionless quantity
